On the Sources of Methane to the Los Angeles Atmosphere

Paul O. Wennberg, Wilton Mui, Debra Wunch, Eric A. Kort, Donald R. Blake, Elliot L. Atlas, Gregory W. Santoni, Steven C. Wofsy, Glenn S. Diskin, Seongeun Jeong, and Marc L. Fischer

ABSTRACT: We use historical and new atmospheric trace gas observations to refine the estimated source of methane (CH₄) emitted into California’s South Coast Air Basin (the larger Los Angeles metropolitan region). Referenced to the California Air Resources Board (CARB) CO emissions inventory, total CH₄ emissions are 0.44 ± 0.15 Tg each year. To investigate the possible contribution of fossil fuel emissions, we use ambient air observations of methane (CH₄), ethane (C₂H₆), and carbon monoxide (CO), together with measured C₂H₆ to CH₄ enhancement ratios in the Los Angeles natural gas supply. The observed atmospheric C₂H₆ to CH₄ ratio during the ARCTAS (2008) and CalNex (2010) aircraft campaigns is similar to the ratio of these gases in the natural gas supplied to the basin during both these campaigns. Thus, at the upper limit (assuming that the only major source of atmospheric C₂H₆ is fugitive emissions from the natural gas infrastructure) these data are consistent with the attribution of most (0.39 ± 0.15 Tg yr⁻¹) of the excess CH₄ in the basin to uncombusted losses from the natural gas system (approximately 2.5–6% of natural gas emissions to basin customers). However, there are other sources of C₂H₆ in the region. In particular, emissions of C₂H₆ (and CH₄) from natural gas seeps as well as those associated with petroleum production, both of which are poorly known, will reduce the inferred contribution of the natural gas infrastructure to the total CH₄ emissions, potentially significantly. This study highlights both the value and challenges associated with the use of ethane as a tracer for fugitive emissions from the natural gas production and distribution system.

INTRODUCTION

Five to six hundred teragrams (Tg) of methane (CH₄) are currently released into the atmosphere each year. Since 1750, the atmospheric abundance of CH₄ has increased from ~700 to 1800 ppb, yielding an increase in the globally averaged radiative forcing of ~0.5 W m⁻², or nearly 1/3 of the total estimated change. The large change in the abundance of CH₄ has likely also altered the concentrations of atmospheric oxidants such as ozone and the hydroxyl radical. While the total CH₄ budget and its trend are well constrained by atmospheric data recorded in situ or from air trapped in polar ice and snow, the individual contributions from its many sources (agriculture, natural wetlands, landfill gas release, energy production, and biomass burning) remain uncertain.

Based on inventory analysis, or bottom-up methods, the United States Environmental Protection Agency (USEPA) estimates that US anthropogenic emissions of CH₄ to the atmosphere in 2009 were 32 Tg. Top-down estimates using measurements of atmospheric CH₄ over the US suggest this number is likely too low by 20% or more. Even using the lower USEPA number, CH₄ accounts for approximately 10% of all US greenhouse gas (GHG) emissions under EPA’s assumption that CH₄ has a 100-year radiative forcing 21 times that of CO₂ by mass (~ 12% using IPCC’s estimate of 25). One of the largest sources of CH₄ in the US are fugitive emissions from natural gas production and use (estimated to be 10 Tg or approximately 3% of the total gas produced). Because CH₄ has such a large radiative forcing relative to CO₂, relatively small losses of CH₄ to the atmosphere can substantially increase the GHG forcing associated with this sector (e.g., 11% fugitive emission (mol/mol) doubles the 100-
year radiative forcing compared to a system in which CH₄ is completely combusted to CO₂. To date, USEPA’s evaluation of these fugitive emissions has focused primarily on losses sustained during energy production, while little attention has been paid to its storage, distribution, and end use.⁴ Current inventory analysis suggests less than 1% is lost from transmission, storage, and distribution.⁴ The California Air Resources Board (CARB) estimates fugitive emissions from the natural gas infrastructure account for only 0.093 Tg/yr or roughly 7% of the total CA CH₄ source of 1.36 Tg/yr.⁶ In this study, we follow up on the studies of Wunch et al. (2009)⁷ and Hsu et al. (2010)⁸ that pointed to large CH₄ emissions from within the greater Los Angeles basin. These reports add to a growing body of evidence for significant CH₄ emissions from urban regions.⁹,¹⁰,¹¹

There are many possible sources of CH₄ within the greater Los Angeles metropolitan area. There are numerous landfills, some still active. In addition, the dairy industry in the east of the basin, wastewater treatment plants, and petroleum production and refineries as well as seeps of natural geogenic CH₄ contribute to the total emissions of CH₄ to the Los Angeles atmosphere. Previous measurements of CH₄, CO, and CO₂ cannot distinguish between the sources. Recent measurements of CH₄ isotopologues by Townsend-Small et al.¹³ suggest, however, that fossil fuels are the main source of CH₄ to the Los Angeles atmosphere.

Most of fossil CH₄ is derived from thermal decomposition of larger hydrocarbons. As a result, a suite of other gases, including C₃H₆, is typically associated with fossil CH₄. With few sources beyond fossil fuel emissions, C₂H₆ has been used extensively as a tracer of such emissions.⁵,¹⁴ Over the past forty years large and increasing quantities of C₂H₆ have been removed from the US and Middle East natural gas for production of ethylene (which in turn is used as a chemical feedstock). As described below, C₂H₆ is declining in the natural gas supply in Los Angeles and now comprises ~2% of the volume. The low and declining ratio of C₂H₆ to CH₄ in the natural gas reflects the increasing value of C₂H₆ whose price is more closely tied with crude oil than natural gas. For example, between 1980 and 2010, US natural gas production increased by 35%, while US production of C₂H₆ increased by more than 300%.¹⁵ In 2010, C₂H₆ production equaled 6% by mass or 3% by volume of increasing value of C₂H₆ whose price is more closely tied with atmospheric concentration of ethane.³,¹⁷

In contrast to fossil CH₄, biogenic production of CH₄ by anaerobic methanogens in landfills, wastewater treatment facilities, or in the guts of ruminants has essentially no associated C₂H₆ production.¹⁴ Thus, simultaneous measurements of CH₄ and C₂H₆ offer one possible tool to partition enhanced CH₄ to either fossil or biogenic sources. Here, we use measurements of C₂H₆ and CH₄ as well as other tracers to investigate the sources of excess CH₄ within the greater Los Angeles Basin.
Wunch et al.7 Here, we extend the analysis to examine the seasonal variations in the ratio of CH₄ to CO (and CO₂).

**Natural Gas Composition Analysis.** The chemical composition of natural gas arriving to the Los Angeles Basin in the major pipelines is measured in situ semicontinuously by gas chromatography using Danalyzers (Daniel Division Headquarters - Houston, Texas, USA). Monthly averages of these data were provided to us by the dominant natural gas supplier to Los Angeles, Southern California Gas Company (May Lew, personal communication). Because we do not know the location of the monitors (each from a different pipeline feeding the basin), we have simply averaged the data for each sampling period to produce an estimate of the ratio of C₂H₆ to CH₄ in the supply gas. We use the mean reported ratio and assume that the true ratio in the natural gas supply as a whole is within 66% of the range of all the measured values (Table 1). During the period of ARCTAS, this ratio was 2.09 ± 0.27% while during CalNex the ratio was 1.65 ± 0.25%. Despite the large uncertainty in the absolute ratio, the reduction between 2008 and 2010 is a robust result as C₂H₆ to CH₄ decreased at all pipeline locations sampled (−20 ± 10%) while the fraction of total natural gas received from each pipeline was similar in 2008 and 2010.²⁴

**Analysis.** All the aircraft data used in our analysis are obtained at altitudes less than 1.5 km within the basin (33.5°–34.5°N; 117°–119°W). To avoid the influence of fire, we only include data where the biomass burning tracer acetonitrile (CH₃CN) is less than 300 ppt. We deinterpolate the data for CO, CO₂, C₂H₆, and CH₄ for each flight using the average of the five lowest values of CH₃CN. These ‘background’ samples are typically from either offshore or at altitudes above the local boundary layer. For C₂H₆, the mean standard deviation of the background values (<110 ppt) is much smaller than the enhancements observed over the basin (1000s ppt). For all the samples taken in each flight, we determine the excess concentration of each gas, ΔX, relative to the background value

\[
ΔX = [X] - [X]₀
\]

where X = CO, CO₂, C₂H₆, or CH₄ and [X]₀ denotes the background concentration of X. While improving the precision of the analysis, the calculation of anomalies relative to these background samples does not alter (within error) the slopes of the gas correlations.

To estimate basin-wide emissions of CH₄ we use the slope of the correlation between ΔCH₄ and ΔCO together with estimates of the CO emissions from CARB.²⁵ This method of estimating the emissions of a gas (using the correlation with CO) does not require that the same source is emitting both gases or even that emissions are geographically collocated. When the lifetimes of gases are long compared to the mixing time within the basin, gases whose sources are distinct will nonetheless be well correlated. Both CH₄ and CO are long-lived, and thus we expect that they will be well correlated - particularly in the afternoon after vertical mixing has helped homogenize the air in the basin. Indeed, previous excess ground-based remote sensing and in situ data from Mt. Wilson have demonstrated that CH₄ and C₂H₆ are highly correlated with CO in the basin.⁷,⁸,²³

To test for spatial representativeness in the aircraft data (i.e., well mixed air masses), we use the ratio of ΔCO to ΔCO₂. The sources of CO are overwhelmingly from automobiles, while those of CO₂ include all sectors in the basin (industrial, residential, mobile). During CalNex, the correlation of ΔCO with ΔCO₂ is high (R²=75%) and ΔCO/ΔCO₂ = 0.82 ± 0.03%, a value broadly consistent with expectation from the basin-wide estimates of the emissions of these gases.⁷ In contrast, the correlation of ΔCO with ΔCO₂ in the ARCTAS measurements that are colocated with the whole air samples are bifurcated (R²=51%). Many of the ARCTAS samples were obtained in the morning at low altitude (<600 m) just offshore. This highly polluted air has a much lower ΔCO/ΔCO₂ (0.28 ± 0.05%). We believe this offshore plume results from advection of the shallow and highly polluted nocturnal boundary layer from the basin. This plume has very high concentrations of numerous hydrocarbons including very short-lived alkenes as well as CFCs and HCFCs. To avoid biasing our analysis by these nonrepresentative samples, we filter the data for ΔCO/ΔCO₂ > 0.70%. The locations of the samples that are removed from our analysis are shown as the open circles in Figure 1. The rest of the ARCTAS samples have a ΔCO/ΔCO₂ broadly consistent with the basin-wide emissions (0.86 ± 0.06%; R²=88%). The ratio ΔCO/ΔCO₂ in 2007/8 is slightly larger

“*The ratio and uncertainty are derived from the variation of the monthly data shown in Figure 2. *²We use the inventory from the California Air Resources Board for 2008 and 2010. Estimate of the emissions in 2007 are interpolated between the 2005 and 2008 inventory. *³Hsu et al.⁸ reported the ratio of methane to CO in flask samples obtained from Mt. Wilson; Gorham et al.²³ reported the ratio of ethane to methane in the same samples. Here we report the ratio of these ratios for the 4 sample periods described in Hsu et al.⁸*"
than in 2010, not inconsistent with the CARB inventory which suggests that CO emissions declined by \(-6\)–\(-8\)% per year between 2005 and 2008 and by \(-5\)% per year between 2008 and 2010 (see Table 2).

During CalNex, the aircraft heavily sampled the dairy area near Chino, CA (33.98 ± 0.05 N; 117.6 ± 0.10 W), shown in the small green box in Figure 1. This area is home to approximately 150,000 dairy cows, approximately 8% of the California dairy.\(^{26}\) We excluded these data (shown as open symbols in Figure 1 and Figure 3) from our analysis to avoid spatial representativeness bias (e.g., to produce a sample set in 2008 and 2010 with a similar geographical distribution).

For a temporal representativeness test, we rely on the nearly continuous year-long total column measurements obtained at JPL in 2007/2008.\(^7\) The slopes of \(\Delta CH_4\) to \(\Delta CO\) seasonally. Further, we see no difference in the correlation between weekdays and weekends (not shown). Thus, consistent with the Hsu et al. and Gorham et al. studies from Mt. Wilson, it appears that the \(CH_4\) emissions do not have strong temporal variations. A similar lack of temporal variability in urban \(CH_4\) emissions was noted by Gioli et al. in their study of Florence, Italy.\(^9\)

In Table 2, we tabulate the observed slope of \(\Delta CH_4\) vs \(\Delta CO\) and \(\Delta C_2H_6\) vs \(\Delta CO\) (as well as slopes to \(\Delta CO_2\)). We include in this table the previously reported data including ground-based in situ measurements obtained on Mt. Wilson, just north of Pasadena,\(^8\) and ground-based remote sensing measurements.\(^7\) For the remote sensing data, the error is derived from

Figure 2. The monthly ratio of \(\Delta CH_4/\Delta CO\) (blue squares, left axis) and \(\Delta CH_4/\Delta CO_2\) (red diamonds, right axis) measured by a remote sensing technique at the campus of NASA’s Jet Propulsion Laboratory (closed symbols) and at the top of Mt. Wilson (open symbols) by in situ sampling.

Figure 3. \(\Delta C_2H_6\) and \(\Delta CH_4\) during the ARCTAS 2008 and CalNex 2010 aircraft campaigns. The solid lines are the best fit lines to the data, and the dashed lines are the ratios of \(C_2H_6\) to \(CH_4\) in the natural gas delivered to the greater Los Angeles basin at the times of the measurements. The open symbols are measurements excluded from this analysis, either because they are samples that explicitly targeted dairy farms or because they were obtained in air with markedly different ratios of \(\Delta CO\) to \(\Delta CO_2\) (see text).
the observed month-to-month variability shown in Figure 2. Uncertainty in the Mt. Wilson data is as reported by the authors of these studies.

Using the CARB CO inventory, the unweighted mean and standard deviation of the resulting CH4 emissions estimates are $0.44 \pm 0.04$ Tg. Additional sources of error include unaccounted for spatial and temporal representation error (perhaps <10% given the consistency of these different approaches) and uncertainty in the emissions of CO (\textasciitilde 10%), suggesting that total annual emissions of CH4 to the basin are $0.44 \pm 0.15$ Tg. Similarly, C2H6 annual emissions are estimated to be $14 \pm 4$ Gg.

A scatter plot of $\Delta$C2H6 plotted as a function of the $\Delta$CH4 is shown in Figure 3 for both the ARCTAS and CalNex campaigns. The observed slopes of $\Delta$C2H6 vs $\Delta$CH4 are listed in Table 2 and shown as the solid line on Figure 3. Errors, listed in Table 2 and illustrated in Figure 4, are calculated using the bootstrap method.27

## DISCUSSION

### Bottom Up Inventory

Shown in Table 3 is an estimate of the sources for CH4 and C2H6 to the Los Angeles Air Basin by sector for 2008. The basin-level CH4 emissions are estimates calculated by summing 0.1 degree (\textasciitilde 10 km) spatial resolution maps of California’s estimated annual average emissions28 for different source sectors over the red box ($-119 < $longitude$ < -117, 33.4 < $latitude$ < 34.3$) that captures the LA Basin (Figure 1). The emissions from landfills are derived from estimates of individual landfills following established methods.29 Emissions from livestock are estimated by scaling livestock density to 2008 total emissions reported of California livestock.6,30 Emissions from wetlands are derived from Potter et al.31 For wastewater, we use the CARB inventory32 for statewide domestic wastewater treatment multiplied by the fraction of state residents using either septic systems or central waste treatment.33 Of the 3.5 million California residents using septic systems, 28% live in the Los Angeles basin (mostly in the east of the basin) yielding 0.010 Tg/yr, while 45% of the California residents using central waste treatment live in the basin yielding 0.009 Tg/yr. In addition, we add 50% of the emission due to statewide wastewater treatment associated with petroleum refining (0.001 Tg/yr). The remainder of the statewide wastewater inventory is associated with agriculture, particularly paper pulp processing; we assume none of the emissions are in the basin. As we have filtered our atmospheric data to avoid biomass burning, we do not include any such emissions here.

For petroleum, the inventory is derived from mandatory reporting of oil extraction and refining to the CARB. In addition, we include the CARB statewide mobile emissions associated with the basin.30 For natural gas, we use an estimate of the fraction of the “Lost-and-Unaccounted-For Gas” from either known fugitive emissions or unaccounted for losses as communicated to us by the Southern California Gas Company (0.02 Tg CH4/yr or approximately 0.1% of deliveries, M.A. Bermel, Southern California Gas Company, personal communication). As only 0.01 Tg of natural gas was produced in the basin in 2009 (in production not associated with petroleum extraction), we neglect this sector.

For C2H6, we assume that only the petroleum and natural gas sectors have associated emissions. For petroleum, we assume that the ratio of C2H6 to CH4 is 10%,14,34 while for the natural
gas sector we use the measured C2H6/CH4 ratio in 2008 from the Southern California Gas Company (Table 1).

In sum, while the bottom-up CH4 inventory (0.212 Tg/yr) accounts for 35–73% of the inferred total emissions to the basin, these sources explain a much smaller fraction of the excess C2H6 (∼15%). To simultaneously close the budget of both gases requires a 0.23 Tg source of CH4 with a C2H6/CH4 molar ratio of 2.6%, a ratio consistent with a source from fossil fuels.

Fossil Fuel Emissions of Methane and Ethane in the Basin. There are two fossil CH4 sources to the basin that need to be better quantified: 1) emissions from underlying geological resource and 2) emissions associated with the imported natural gas.

The Los Angeles Basin overlays a large number of petroleum and gas rich sediments. In 2009, 0.22 Tg of natural gas was produced in the basin (approximately 2% of the gas consumed) — the vast majority associated with petroleum production. In addition, there are numerous capped wells from historical gas and oil production. The CARB inventory suggests, however, that the methane (and, by inference, the C2H6) emissions from this sector are small (Table 3). If the emissions from petroleum production or from emissions of capped wells are much higher than reported, this sector could be an important contributor to both the C2H6 and CH4 budgets.

In a heterogeneous environment such as Los Angeles, it is not straightforward to find unique tracers of the geological gas emissions. For example, while the ratio of propane to C2H6 in Los Angeles air (∼1) is similar to the ratio measured in many of the gas and petroleum fields and much higher than in the natural gas supply (∼0.17), large amounts of propane are sold in Los Angeles (∼0.6 Tg/yr). Gorham et al. estimate of 71 tons of propane emitted into the basin each day thus represents only ∼4% of the supply. Indeed, elevated propane is found in many cities that have no known geological sources.

Emissions from the natural gas infrastructure are estimated by the Southern California Gas Company to be very small. Nevertheless, it is striking how similar the slope of ∆C2H6 vs ∆CH4 is to the ratio of these gases in the natural gas supply (shown as dashed lines in Figure 3). In addition, the change in the observed ratio between 2008 (ARCTAS) and 2010 (CalNex) is of the same sign and magnitude as the reduction in the amount of C2H6 in the natural gas.

To estimate the upper limit to the contribution of emissions from the imported natural gas to the total sources of methane, we use the ratio of ethane to methane in ambient air and in the gas supply. Assuming that the only significant source of C2H6 to the Los Angeles atmosphere is fugitive emissions of natural gas, the maximum emissions of CH4 into the atmosphere from natural gas, NG, are

$$E_{\text{max}}(\text{CH}_4, \text{NG}) = E(\text{CH}_4) \times (\beta/\alpha)$$

where $\alpha$ is the ratio of C2H6 to CH4 in the natural gas (Table 1), and $\beta$ is the same ratio in ambient air. The values of $\beta$ are reported in Table 2. Clearly, if the only emissions of C2H6 are from uncombusted natural gas supplied to the basin, most of the ∆CH4 in the basin is also derived from this source. The average $E_{\text{max}}(\text{CH}_4, \text{NG})$ is 0.39 ± 0.15 Tg where the error is dominated by the systematic uncertainty in $\alpha$ (Table 2).

We show in Figure 1 the mixing ratio of ∆CH4 not explained by ∆C2H6, [∆CH4]∗

$$[\Delta \text{CH}_4]^* = \Delta \text{CH}_4 - 1/\alpha(\Delta \text{C}_2\text{H}_6)$$

The circles are from 2008 while the triangles are from 2010. The larger symbols are locations where ∆C2H6 is greater than 4 ppb. The only obvious source of CH4 not associated with ∆C2H6 is in the east of the basin near Chino, California (red open triangles within the green box), where a large concentration of dairy farms is located. Samples obtained near landfills (e.g., Scholl Canyon (34.16N,118.19W)) and near the large Hyperion wastewater treatment plant (33.92N,118.43W) show no obvious CH4 enhancements above those explained by C2H6, though the sampling is admittedly sparse and wind will certainly advect these emissions away from their source.

Southern California Gas Company delivers natural gas to the Los Angeles Basin and the surrounding area. Approximately 30% of its gas is delivered to residential customers (5.4 Tg/yr), 30% to industrial and commercial customers (5.6 Tg/yr), 37% to electric utilities (6.9 Tg/yr), and the remainder to natural gas vehicles and enhanced oil recovery steaming (0.5 Tg/yr). Assuming that this distribution of gas is the same inside the Los Angeles Basin (which includes Los Angeles, San Bernardino, Orange, and Riverside Counties), an emission of 0.39 Tg represents approximately 3.5% of the gas delivered to customers in the basin (∼11 Tg in 2007). Southern California Gas Company also deliveres to Fresno, Imperial, Kern, Kings, Santa Barbara, San Luis Obispo, Tulare, and Ventura Counties, which are less densely populated, are not located in the basin, and consume an additional 1 Tg for residential customers and 6 Tg for nonresidential customers. Southern California Gas Company, however, operates several large storage facilities within the basin. Thus, using the total volume flowing through pipelines in the basin as a denominator, 0.39 Tg represents approximately 2% of the gas flowing into the basin.

As mentioned above, however, mass balance estimates by Southern California Gas Company suggest that only ∼0.1% of the natural gas is lost between the city gates and the customer meters (M. A. Bermel, Southern California Gas Company, personal communication). This suggests that if the methane emissions in Los Angeles are associated with the natural gas infrastructure, such losses must occur post consumer metering. Losses of gas within both homes and businesses are certainly one possible explanation for our findings. Steady but very small leaks from gas fittings and valves could contribute a significant fraction of the total gas used in these settings. Indeed, it is highly likely that the vast majority of all valves and fittings between the gas wells and the end-use gas appliances are located at the very end of the delivery system, e.g. in customers’ homes and businesses. For example, the first author’s home (constructed in 1914) contains no fewer than 100 gas fittings; seven ball valves, and, within the appliances themselves, eight control/throttle valves; several had obvious leaks. Yet, the duty cycle of appliance use is very low — just a few percent of the time is any gas appliance in use. Thus, small steady leaks could amount to a few percent of the total consumed. Such leaks would produce only a small enhancement in methane in the home and would not be detectable by smell or constitute, in any way, a health or fire hazard. For example, consider a 150 m² home that uses 1000 m³ of gas annually and has one air exchange each hour. If 5% of the natural gas usage is lost unburned into the home (less than the use of a typical pilot light), methane concentrations would only be about 12 ppm higher than in the ambient air outside the home; the odorant concentration would be orders of magnitude below the threshold necessary to smell the gas. If such high leakage...
rates occurred across the US, losses within the distribution system would represent a source of more than 6 Tg/year. This additional source of CH₄ would go a substantial way toward reconciling the top-down and inventory estimates of total US CH₄ sources. Electronic gas metering is currently being installed throughout Southern California Gas Company’s service area, and these data may provide a rapid and noninvasive method of evaluating whether some or many customers have unrealistically large and steady natural gas consumption.

**Outlook for Future Studies.** Emissions of methane from Los Angeles are substantial and considerably larger than current inventories suggest. The correlation between methane and ethane within the basin point suggest fossil fuel emissions as the likely source of much of the unaccounted for source. We are unable, however, to definitively determine whether these emissions are associated with imported gas or emissions from the underlying geological resource. The obvious next step is to undertake in situ sampling to seek out sources of methane within Los Angeles and more broadly in a cross section of urban centers, in an extended version of the work by Baker et al. These measurements should include a suite of hydrocarbons and perhaps sulfur compounds together with an associated inventory of possible sources, including natural gas.
